ABSTRACT

Cement grouting is an operation often carried out to consolidate and seal the rock mass in dam sites and tunnels. The quality and efficiency of a grouting operation depends on various factors such as water take, grout properties and grouting pressure. One of the most effective parameters on quality and efficiency is pressure. Application of excessive pressure causes hydraulic fracturing in the rock mass and a low pressure leads to incomplete grouting and failure to seal the site in a perfect manner. In this study, mathematical modeling was used for the first time to predict and determine the optimal pressure. Thus, the joints that existed in the rock mass were simulated using cylindrical shell model. The joints’ surroundings were also modeled through the Pasternak environment. To obtain equations governing the joints and the surroundings, the energy method was applied using the Hamilton principle. Finally, an analytical solution method was used to obtain the maximum grouting pressure. In order to validate the modeling, the grouting pressure values obtained by the model were used on the Seymareh and Aghbolagh dams and the relative error rates were measured considering the differences between the calculated and actual pressures. Modeling the examined sections of Seymareh dam showed 29.61, 5.57, 21.98, 32.50 and 9.09 percent error rates and for that of the Aghbolagh dam were 4.32, 5.40 and 2.96 percent. The results indicate that this modeling can be used to estimate the pressure of hydraulic fracturing in grouting operation, and also to prevent its excessive values.

Keywords : Hydraulic fracturing, Mathematical modeling, Cylindrical shell model, Seymareh and Aghbolagh dams

1. Introduction

Generally, cement grouting operation is one of the ways to reduce water leakage, increase strength and consolidate rock joint on the site [1]. In this process, cement grout passes through the grouting section and causes the rock mass to become consolidated and sealed. One of the effective factors on determining the grout penetration distance and increasing operation efficiency is the grouting pressure [2]. By definition, the grouting pressure is the maximum permitted pressure applied at each step of the grouting process by a pump. The range of this pressure usually starts from the minimum required rate for the grout to penetrate into the joints and reaches its maximum permitted value at the end of operation [3]. However, the pressure fluctuates and changes on the hydraulic path between the pumps and the sections, and this point must be taken into account in calculations [4].

There are two main theories regarding the pressure rate: the first is grouting with high pressure in order to increase the influence radius in which the operational expenses are reduced and fewer boreholes are needed [5]. There is also a second theory proposed by other scientists that suggest grouting with low pressure since applying high pressure causes hydraulic fracture in the rock mass and decreases the rock quality [6]. Determining an appropriate range for this parameter has an essential role in the effectiveness of operations [7]. Since a precise criterion or relation has not yet been proposed to determine the suitable pressure, the pressure estimation has always been carried out as an absolutely empirical practice by contractors in workshops [8]. Thus, conducting studies and research projects on this topic is indispensable if one wants to define a certain criterion or scale that contributes to the selection of optimum pressure [9].

After hydrogeological, topographical, geological and geotechnical tests, the grouting pressure is determined for different depths in the ground [10]. The applied pressure is proportionate to the depth of grouting, grout properties, the grouting technique, rock penetrability, jointed rock properties, the status of local stresses, structure dimensions and the physical and mechanical properties of the rock mass. Pgw or pressure at the grouting section is calculated using the relation in (1) [11].

\[ Pgw = Pmg + P_{hy} - (\frac{Dg}{2} + f_{u} + f_{w}) \]  

In this relation, Pmg is the grout pressure on barometer at the top of the borehole which is called the grouting manometric pressure in MPa; P_{hy} is the hydrostatic pressure caused by the height of the grout’s fluid column in Mpa; P_{gw} is the hydrostatic pressure resulted from the height of the underground water column at the grout section in Mpa and f_{u} and f_{w} are pressure losses of the grout caused by pipes and fittings in MPa, respectively [12]. The last two values are negligible if obtaining them in shallow boreholes is impossible [13]. However, when multiple connections are used or the length of the borehole is considerable, those values must be calculated based on the physical properties of the pipe such as its diameter and its composing material, as well as the connections properties. The value of P_{gw} can be adjusted and read using a manometer. The values of Pmg and P_{gw} can be calculated through relations (2) and (3) [14]:

\[ Pmg = \gamma_s (D_g + L_g/2) \sin \alpha + H_{mg} \]  

\[ Pgw = \gamma_s ((D_g + L_g/2) \sin \alpha - D_{gw}) \]
γ_s is the special weight of the grout. It is the gravitational constant
timed the specific gravity and can be stated in form of meganewtons per
cubic meter [15]. L is the length of the section in meters and D_e is the
distance in meter between the section’s upper level in the downward
borehole and the point at which excavation started [16]. D_m is the depth
of groundwater vertical to the base level in meter, α is the gradient of
the borehole, H_m is the vertical distance of the manometer from the
groundwater level compared to the base level in meter and γ_w is the
special weight of water in meganewtons per cubic meter (Fig. 1) [17].

3.1. Stress-strain relations

Shear strains γ_u, γ_v are considered negligible in the Kirchhoff
deformation theory. Hence, the tangential displacements u and v
become the linear functions of the radial coordinate (z) [23]. In other
words,

\[ u(x, \theta, z) = u(x, \theta) - z \frac{\partial v(x, \theta)}{\partial x}, \]
\[ v(x, \theta, z) = v(x, \theta) - z \frac{\partial u(x, \theta)}{\partial \theta}, \]
\[ w(x, \theta, z) = w(x, \theta). \]

(5)

The strain components \( \varepsilon_{xx} \), \( \varepsilon_{yy} \) and \( \gamma_{xy} \) at an arbitrary point of the
shell are related to the middle surface strains \( \varepsilon_{xx}, \varepsilon_{yy} \) and \( \kappa_{xy} \)
by the following relationships:

\[
\begin{bmatrix}
\varepsilon_{xx} \\
\varepsilon_{yy} \\
\gamma_{xy}
\end{bmatrix}
= \begin{bmatrix}
C_{11} & C_{12} & 0 \\
C_{12} & C_{22} & 0 \\
0 & 0 & C_{66}
\end{bmatrix}
\begin{bmatrix}
\frac{\partial u}{\partial x} \\
\frac{\partial v}{\partial x} + \frac{w}{R} \\
\frac{\partial w}{\partial x}
\end{bmatrix}
- \frac{z}{R^2} \begin{bmatrix}
\frac{\partial^2 w}{\partial x^2} \\
\frac{1}{R} \frac{\partial^2 w}{\partial \theta \partial x} \\
\frac{1}{R} \frac{\partial^2 w}{\partial \theta^2}
\end{bmatrix}
\]

(6)

Where \( u, v \) and \( w \) describe the displacements in the orthogonal
coordinate system \( x, \theta, z \) established at the middle surface of the shell.

Using Hook law, the constitutive equation may be expressed as follows (Ghorbanpour Arani, 2011a, 2011b):

\[
\begin{bmatrix}
\sigma_{xx} \\
\sigma_{yy} \\
\sigma_{xy}
\end{bmatrix}
= \begin{bmatrix}
C_{11} & C_{12} & 0 \\
C_{12} & C_{22} & 0 \\
0 & 0 & C_{66}
\end{bmatrix}
\begin{bmatrix}
\frac{\partial u}{\partial x} \\
\frac{\partial v}{\partial x} + \frac{w}{R} \\
\frac{\partial w}{\partial x}
\end{bmatrix}
- \frac{z}{R^2} \begin{bmatrix}
\frac{\partial^2 w}{\partial x^2} \\
\frac{1}{R} \frac{\partial^2 w}{\partial \theta \partial x} \\
\frac{1}{R} \frac{\partial^2 w}{\partial \theta^2}
\end{bmatrix}
- \frac{1}{2} \begin{bmatrix}
\frac{\partial^2 w}{\partial x^2} \\
\frac{1}{R} \frac{\partial^2 w}{\partial \theta \partial x} \\
\frac{1}{R} \frac{\partial^2 w}{\partial \theta^2}
\end{bmatrix}
\]

(7)

Where \( \sigma_{ij}, i, j = x, \theta, z \) stresses as well as \( u, v, w \) are the displacements
of an arbitrary point of the shell in axial, circumferential and radial
directions, respectively. Also, \( C_{ip}, i, j = 1, \ldots, 6 \) correspond to elastic
constants [23].

3.2. Energy method

The total potential energy of the pipe is the sum of strain energy,
kinetic energy and work conducted by flowing fluid. The strain energy
is [23]:

\[
U = \frac{1}{2} \sum_{i=1}^{3} \sigma_{ij} \varepsilon_{ij} + \frac{1}{2} \sigma_{ij} \frac{\partial^2 u}{\partial x^2} + \frac{1}{2} \sigma_{ij} \frac{\partial^2 v}{\partial x \partial \theta} + \frac{1}{2} \sigma_{ij} \frac{\partial^2 w}{\partial x \partial z} + \frac{1}{2} \sigma_{ij} \frac{\partial^2 w}{\partial \theta^2}
\]

(8)

and the kinetic energy is:

\[
K = \frac{1}{2} \int \left( \frac{1}{\rho} \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 v}{\partial x \partial \theta} + \frac{\partial^2 w}{\partial x \partial z} + \frac{\partial^2 w}{\partial \theta^2} \right) dV,
\]

(9)

and the work conducted by internal viscous fluid is (Wang and Ni,
2009):

\[
W = \frac{1}{2} \left( p_{int} \frac{\partial^2 u}{\partial x^2} + \frac{1}{\rho} \frac{\partial^2 v}{\partial x \partial \theta} + \frac{1}{\rho} \frac{\partial^2 w}{\partial x \partial z} + \frac{1}{\rho} \frac{\partial^2 w}{\partial \theta^2} \right) \int dA.
\]

(10)

Now, by replacing these terms in the following expression, based on
Hamilton principal:

\[
\int (\delta U + \delta W) dt = 0,
\]

(11)

and defining the following non-dimensional quantities:

Fig. 1. Grout penetration and hydraulic fracturing in the rock mass [18].

2. Relationship between water take rate in the water pressure test and the amount of grout used in grouting of hydraulically fractured rocks

Water pressure test is used before grouting operation to determine
the rate of penetrability, the necessity of grouting and estimations
related to it, and the amount of sealing caused by grouting. In this test,
the rate of hydraulic conductivity of the rock mass is specified by the
penetration of water into the borehole [18]. On some sites, there are
rock masses in which the recorded water take in the pressure test is low
while the amount of recorded cement grout in the grouting operation is
high [19]. However, the joints with low rate of penetrability must
naturally be inclined to absorb little grout. It is because the hydraulic
fracturing phenomenon occurs as a result of too much grouting
pressure. Hydraulic fracturing causes joints with little opening to widely
open or creates new fractures [20]. Therefore, understanding hydraulic
fracturing can be helpful in determining is the reason of difference in
the rate of water take and cement grout in these two operations. In the
water pressure test, the amount of water that enters the pit under certain
pressure is recorded. Absorption of one-liter water per minute for each
meter of the borehole at the pressure of one mega Pascal is equal to
lugeon [21].

1LU=1lit.min⁻¹.m⁻¹

Lugeon number is always ranges between one and 100 and the value
higher than 100 are considered equal to 100:

LU=10Q/Pe

where Q is the quantity of the water absorbed in liters per meter per
minute, Pe is the highest effective pressure in the test and LU is the
lugeon value [22].

3. Mathematical modeling

A schematic diagram of a cylindrical shell is shown in Fig. 2 in which
geometrical parameters such as length (L), radius (R) and thickness (h)
are also indicated. The surrounding foundation is simulated with spring
and shear constants.

Fig. 2 A schematic figure of an embedded cylindrical shell [23].
the four electro-thermo mechanical coupling governing equations of PVDF cylindrical shell conveying viscose fluid, can therefore be written as [24]:

\[
\begin{align*}
\rho \frac{\partial u}{\partial t} &+ \rho \beta \frac{\partial \theta}{\partial t} = \nabla \cdot (\sigma + p I) + f_i \\
\rho \frac{\partial v}{\partial t} &+ \rho \beta \frac{\partial \theta}{\partial t} = \nabla \cdot (\tau + p I) + f_j,
\end{align*}
\]

where \(\sigma = C_{ij} \epsilon_{ij}\) and \(\tau = C_{ij} \gamma_{ij}\), and \(\epsilon_{ij}, \gamma_{ij}\) are the strain and stress tensors, respectively, \(C_{ij}\) is the elastic moduli tensor, \(\rho\) is the mass density, \(\beta\) is the temperature expansion coefficient, \(p\) is the fluid pressure, and \(f_i, f_j\) are the external forces per unit mass.

4. Navier method

Simply considering the supported boundary condition, the mechanical displacement may be written as [24]:

\[
w(x, t) = w_0 \sin \left( \frac{nx}{L} \right) \sin (nt \theta),
\]

\[
u(x, t) = u_0 \cos \left( \frac{nx}{L} \right) \sin (nt \theta),
\]

\[
u(x, t) = v_0 \sin \left( \frac{nx}{L} \right) \cos (nt \theta),
\]

Substituting Eq. (12) into Eqs. (9) - (11) results in:

\[
\begin{bmatrix}
K_{11} & K_{12} & K_{13} \\
K_{21} & K_{22} & K_{23} \\
K_{31} & K_{32} & K_{33}
\end{bmatrix}
\begin{bmatrix}
u_0 \\
w_0
\end{bmatrix}
= \begin{bmatrix}
u(x, t) \\
w(x, t)
\end{bmatrix},
\]

The displacement may be obtained by solving the equation above. Using the obtained displacement and Eq. (10), the fluid pressure can be calculated [24].

5. Modeling Details

The parameters shown in Table 1 were inserted into the mathematical model as the input data.

6. Case study

6.1. Seymareh dam

Seymareh dam and its power plant are located 40 km northwest of Dareshahr city and 7.5 km from Chesheh Shirin village in Ilam province, Iran. Its purpose is to use the potential power in Seymareh River. Seymareh is a thin double-arched concrete dam with the height of 130m from the current river bed (and about 180m from the bedrock). The dam crest elevation is 730 m, and at the normal elevation, the water height is 720 m above the sea level. The length of the dam crest at its elevated part is 202 m. The capacity of the dam reservoir is 3.21 billion cubic meters.

First of all, in order to examine the rate of rock penetrability, the water pressure test was carried out on boresoles. Then, when the rate of hydraulic conduction in the rock environment was specified, the cement grouting operation was performed to seal the base and support of the dam. In Table 2, some results of water take and cement grout in boreholes P-19, P-20, P-22 and P-23 are shown. According to these data, it can be seen that in borehole P-19 in sections 3 and 4, in borehole P-20 in section 6, in borehole P-22 in section 4 and in borehole P-23 in section 11, the rate of water takes obtained by lugeon number is low while the cement grout take is high. Generally, this difference in water take and cement take processes indicates the occurrence of hydraulic fracturing phenomenon due to the excessive pressure in the cement grouting procedure.

6.2. Aghbolaghat dam

Aghbolaghat earth dam is located 32 km in south of the Borujen City in Chahar Mahal-o-Bakhhtiari province in Iran. The geographical coordinates of the dam axis in the UTM system are x=520363 and y=3512353. Considering the geological map, the area of interest is located in the Zagros mountain range under the over-thrust zone.

From a stratigraphic perspective, the Mesozoic, Cenozoic and particularly the Cretaceous rocks are dominant in this zone, and from a structural point of view, large faults such as the main Zagros fault and Dena fault play major roles in the zone.

In this site, pilot grouting operation was conducted in the limestone units on the right side of the dam as the most important part of the whole grouting process with respect to sealing. The arrangement of TG-1, TG-2 and TG-3 grouting boreholes is in such a form that they are placed on the vertices of an equilateral triangle each side of which is three meters long. In each borehole, lugeon experiments are conducted first. After obtaining the results, plans for the mixture of water, cement and other additives are selected. Grouting operation is carried out in five-meter-long sections and the results are shown in Table 3.

According to the results shown in Table 3, we can see that in the depths of 25-30 and 30-35 meters in borehole TG-1, the rate of water take is low (LU=2) while the amount of the grouted cement is high. The values of aforementioned variables are 1175 and 1325, respectively. In the depth of 32-35 meters in borehole TG-2, the water take was also low (LU=2) but the cement take was very high and equaled 2466 kg. The difference between low water absorption compared to high grout take indicates excessive increase in the cement grout's penetration pressure and occurrence of hydraulic fractures in the grouting process.

7. Results of modeling

In this section, based on the results obtained from the water pressure test and grouting operation on the Seymareh and Aghbolagh dams and comparing the real pressure values with the calculated pressure acquired through modeling, the results achieved by modeling were validated. The resulting information consists of pressure values in the boreholes where water take in the water pressure test is low while grout take in the grouting operation is high. This shows that hydraulic fracturing has occurred in these sections. These data are shown in Table 4. In Fig 3, the
degree of convergence among these values is shown.

### 8. Comparison and analysis of the results

According to the results shown in Fig. 2, it can be seen that there is a high degree of convergence between the values of the real recorded pressure in Seymareh dam-construction workshops and the values measured through modeling. In order to validate the modeling, relative error of the measured pressure (P<sub>fracturing</sub>) was compared to the real recorded pressure (P<sub>real</sub>) obtained from E= [(P<sub>real</sub>-P<sub>fracturing</sub>)]/P<sub>real</sub>*100. The results are shown in Table 4.

The results shown in Tables 2 and 4 indicate that there is a desirable correlation between calculated fracturing pressure and the fracturing pressure recorded in the Seymareh and Aghbolagh dam-construction.
sites. This shows that the proposed model has the desirable precision in predicting and estimating the rate of hydraulic fracturing.

9. Sensitivity analyses

In this section, sensitivity analyses were conducted to understand the effect of model parameters on the response. For this purpose, the statistical analysis by SPSS software was also used. In this analysis, the most important parameters for estimation of the grout pressure that are obtained from cores and grouting boreholes in dam-sites include the joint aperture (b), density of the rock (d), shear stiffness coefficient (scc), elasticity module (E), Poisson’s ratio (pc). SPSS software was used in this section to analyze the relationship between the dependent parameter (P) and the independent variables and to determine the effects of independent parameters in estimation of grouting pressure. This analysis was used based on the data obtained from grouting sites. A sample of the output data from the software was illustrated in Tables 5 and 6.

Table 5. The results in SPSS output: the multiple correlation coefficient R and the square of the multiple correlation coefficient R² and Adjusted R Square and std. Error of the Estimate.

In Table 6, column B, unstandardized coefficients for the independent variables shows the effectiveness of the parameters to estimate the grouting pressure. It can be seen that the most effective parameters are joint aperture (b), density of the rock (d), shear stiffness coefficient (scc), elasticity module (E) and Poisson’s ratio (pc), respectively.

10. Conclusion

The required rate of grouting pressure to prevent the hydraulic fracturing phenomenon was examined in this study. Not only the occurrence of hydraulic fracturing practically prevents achieving the goals of grouting, namely sealing and improving the site, but it also causes most of the joints to open, creates fractures in the rock mass, and deteriorates its quality. Therefore, it is highly important to estimate the rate of grouting pressure which causes fracturing. To do so, mathematical modeling and simulation of the joint conditions were conducted using a cylindrical shell and the fracturing pressure was calculated. In order to validate the results, real values of hydraulic fracturing pressure recorded in grouting operations in the Seymareh and Aghbolagh dams were used and the processes of change in real pressure values and calculated pressure values were controlled. The results showed that there were desirable convergence and correlation between these two sets of values. In addition, calculation of the relative error between the values showed that the mathematical model in the sections of the Seymareh dam had the error values of 29.61, 5.57, 21.98, 32.50 and 9.09 percent and in the Aghbolagh dam sections, the error values were to be 4.32, 5.40 and 2.96 percent. These results indicate that mathematical modeling can be used to predict the occurrence of hydraulic fracturing phenomenon in grouting operations and thus increase the efficiency and productivity of such processes. In order to understand the effect of model parameters on the response, sensitivity analysis by SPSS software was conducted. Results showed that the most effective parameters are joint aperture (b), density of the rock (d), shear stiffness coefficient (scc), elasticity module (E) and Poisson’s ratio (pc) respectively.
